Chapter 1

What is Perceptron?

In machine learning, the perceptron is an algorithm for supervised classification of an input into one of several possible non-binary outputs. It is a type of linear classifier, i.e. a classification algorithm that makes its predictions based on a linear predictor function combining a set of weights with the feature vector. The algorithm allows for online learning, in that it processes elements in the training set one at a time.

The perceptron algorithm dates back to the late 1950s; its first implementation, in custom hardware, was one of the first artificial neural networks to be produced.

1.1 A Bit of History

The perceptron algorithm was invented in 1957 at the Cornell Aeronautical Laboratory by Frank Rosenblatt, funded by the United States Office of Naval Research.

1.2 Definition

In the modern sense, the perceptron is an algorithm for learning a **binary classifier**: a function that maps its input x (a real-valued vector) to an output value f(x) (a single binary value):

$$f(x) = \begin{cases} 1 : & w.x + b > 0 \\ 0 : & otherwise \end{cases}$$

where...
- **w** is a vector of real-valued weights,
- $\mathbf{w} \cdot \mathbf{x}$ is the dot product (which here computes a weighted sum), and **b** is the 'bias',
- a constant term that does not depend on any input value.

If b is negative, then the weighted combination of inputs must produce a positive value greater than $|b|$ in order to push the classifier neuron over the 0 threshold. Spatially, the bias alters the position (though not the orientation) of the decision boundary. The perceptron learning algorithm does not terminate if the learning set is not linearly separable. If the vectors are not linearly separable learning will never reach a point where all vectors are classified properly. The most famous example of the perceptron's inability to solve problems with linearly nonseparable vectors is the Boolean exclusive-or problem.

In the context of neural networks, a perceptron is an **artificial neuron** using the **Heaviside step function** as the activation function. The perceptron algorithm is also termed the **single-layer perceptron**, to distinguish it from a multilayer perceptron, which is a misnomer for a more complicated neural network. As a linear classifier, the single-layer perceptron is the **simplest feedforward neural network**.

1.3   Learning Algorithm

Below is an example of a learning algorithm for a (single-layer) perceptron. For multilayer perceptrons, where a hidden layer exists, more sophisticated algorithms such as **backpropagation** must be used. Alternatively, methods such as the **delta rule** can be used if the function is **non-linear** and **differentiable**, although the one below will work as well.

When multiple perceptrons are combined in an artificial neural network, each output neuron operates independently of all the others; thus, learning each output can be considered in isolation.

1.3.0.1 Definition

We first define some variables:
- $y = f(\vec{z})$ denotes the output from the perceptron for an input vector $\vec{z}$.
- **b** is the bias term, which in the example below we take to be 0.
- $D = \{\vec{X}_1, d_1), \ldots, (\vec{X}_s, d_s)\}$ is the training set of s samples, where:
  - $\vec{X}_j$ is the n-dimensional input vector.
  - $\mathbf{d_j}$ is the desired output value of the perceptron for that input.

  We show the values of the features as follows:
- $x_{j,i}$ is the value of the ith feature of the jth training input vector.
- $x_{j,0} = 1$.

  To represent the weights:
- w_i is the ith value in the weight vector, to be multiplied by the value of the ith input feature.
- Because $x_{j,0} = 1$, the w_0 is effectively a learned bias that we use instead of the bias constant b.

  To show the time-dependence of **w**, we use:
- $w_i(t)$ is the weight i at time t.
- α is the learning rate, where $0 < \alpha \leq 1$.
  Too high a learning rate makes the perceptron periodically oscillate around the solution unless additional steps are taken.

1.3.1 Steps

1. Initialise the weights and the threshold. Weights may be initialised to 0 or to a small random value. In the example below, we use 0.
2. For each example j in our training set D , perform the following steps over the input $\mathbf{x}_j$ and desired output d_j :
   a) Calculate the actual output:
      $$\mathbf{y_j(t) = f[w(t) \cdot x_j] = f[w_0(t) + w_1(t)x_{j,1} + w_2(t)x_{j,2} + \cdots + w_n(t)x_{j,n}]}$$
   b) Update the weights:
      $$\mathbf{w_i(t+1) = w_i(t) + \alpha(d_j - y_j(t))x_{j,i}} \quad \text{for all feature } \mathbf{0 \leq i \leq n}.$$
3. For offline learning, the step 2 may be repeated until the iteration error $\frac{1}{s}\sum_{j=1}^{s} |\mathbf{d_j - y_j(t)}|$ is less than a user-specified error threshold γ, or a predetermined number of iterations have been completed.

The algorithm updates the weights after steps $2a$ and $2b$. These weights are immediately applied to a pair in the training set, and subsequently updated, rather than waiting until all pairs in the training set have undergone these steps.

1.4   Convergence

The perceptron is a linear classifier, therefore it will never get to the state with all the input vectors classified correctly if the training set $\mathbf{D}$ is not linearly separable, i.e. if the positive examples can not be separated from the negative examples by a hyperplane.

1.5   Pocket Algorithm

The pocket algorithm with ratchet (Gallant, 1990) solves the stability problem of perceptron learning by keeping the best solution seen so far "in its pocket". The pocket algorithm then returns the solution in the pocket, rather than the last solution. It can be used also for non-separable data sets, where the aim is to find a perceptron with a small number of misclassifications.

1.6   Example

A perceptron learns to perform a binary NAND function on inputs x_1 and x_2 .

- Inputs: x_0 , x_1 , x_2 , with input x_0 held constant at 1.
- Threshold (θ): 0.5
- Bias (b): 0
- Learning rate (r): 0.1
- Training set, consisting of four samples: $\{((1, 0, 0), 1), ((1, 0, 1), 1), ((1, 1, 0), 1), ((1, 1, 1), 0)\}$

In the following, the final weights of one iteration become the initial weights of the next. Each cycle over all the samples in the training set is demarcated with heavy lines.

1.7 Example : *aja/example/ann/perceptron_network.cpp*

In our C++ implementation of this network, we have the following classes: we have separate classes for input neurons and output neurons. The **input_neuron** class is for the input neurons. This class has weight and activation as data members. The **output_neuron** class is similar and is for the output neuron. It is declared as a friend class in the **input_neuron** class. The output neuron class has also a data member called output. There is a network class, which is a friend class in the **output_neuron** class. An instance of the network class is created with four input neurons. These four neurons are all connected with one output neuron.

1.7.0.1 input_neuron class

The member functions of the input_neuron class are:
• A default constructor,
• A second constructor that takes a real number as an argument, and
• A function that calculates the output of the input neuron.

The constructor taking one argument uses that argument to set the value of the weight on the connection between the input neuron and the output neuron. The functions that determine the neuron activations and the network output are declared public. The activations of the neurons are calculated with functions defined in the neuron classes. A threshold value is used by a member function of the output neuron to determine if the neurons activation is large enough for it to fire, giving an output of 1.

1.7.0.2 Implementation of Functions

The network is designed to have four neurons in the input layer. Each of them is an object of class input_neuron, and these are member classes in the class network. There is one explicitly defined output neuron of the class out_neuron. The network constructor also invokes the neuron constructor for each input layer neuron in the network by providing it with the initial

weight for its connection to the neuron in the output layer. The constructor for the output neuron is also invoked by the network constructor, at the same time initializing the output and activation data members of the output neuron each to zero. To make sure there is access to needed information and functions, the output neuron is declared a friend class in the class input_neuron. The network is declared as a friend class in the class out_neuron.

1.7.0.3   Input/Output

There are two data files used in this program. One is for setting up the weights, and the other for setting up the input vectors. On the command line, you enter the program name followed by the weight file name and the input file name. You can find a file called weight.dat, which contains the following data:
2.0 3.0 3.0 2.0
3.0 0.0 6.0 2.0
These are two weight vectors.
You can find a file called input.dat with the two data vectors below:
1.95 0.27 0.69 1.25
0.30 1.05 0.75 0.19

1.7.1   Execution

Listing 1.1: perceptron_netwotk.cpp output

```
This program is for a perceptron network with
input layer of 4 neurons, each connected to the
output neuron.

This example takes Real number as Input Signals
Please enter the number of weights/vectors : 2
This is vector # 1
Please enter a threshold value for
output neuron, eg 7.0 : 7
```

```
Input neuron 1 value is : 1.95 weight is : 2
and its activation is : 3.9
Input neuron 2 value is : 0.27 weight is : 3
and its activation is : 0.81
Input neuron 3 value is : 0.69 weight is : 3
and its activation is : 2.07
Input neuron 4 value is : 1.25 weight is : 2
and its activation is : 2.5

Output neuron activation is : 9.28

The output neuron activation exceeds the−
threshold value of 7
Output value is 1

This is vector # 2
Please enter a threshold value for
output neuron , eg 7.0 : 7

Input neuron 1 value is : 0.3 weight is : 3
and its activation is : 0.9
Input neuron 2 value is : 1.05 weight is : 0
and its activation is : 0
Input neuron 3 value is : 0.75 weight is : 6
and its activation is : 4.5
Input neuron 4 value is : 0.19 weight is : 2
and its activation is : 0.38

Output neuron activation is : 5.78

The output neuron activation is smaller than the−
threshold value of 7
Output value is 0
```
